## Abstract

The MINERVA-Australis telescope array is a facility dedicated to the follow-up, confirmation, characterization, and mass measurement of planets orbiting bright stars discovered by the *Transiting Exoplanet Survey Satellite* (TESS)—a category in which it is almost unique in the Southern Hemisphere. It is located at the University of Southern Queensland's Mount Kent Observatory near Toowoomba, Australia. Its flexible design enables multiple 0.7 m robotic telescopes to be used both in combination, and independently, **for high-resolution spectroscopy and precision photometry of TESS transit planet candidates**. MINERVA-Australis also enables complementary studies of exoplanet spin-orbit alignments via Doppler observations of the Rossiter-McLaughlin effect, radial velocity searches for nontransiting planets, planet searches using transit timing variations, and ephemeris refinement for TESS planets. In this first paper, we describe the design, photometric instrumentation, software, and science goals of MINERVA-Australis, and note key differences from its Northern Hemisphere counterpart, the MINERVA array. **We use recent transit observations of four planets, WASP-2b, WASP-44b, WASP-45b, and HD 189733b, to demonstrate the photometric capabilities of MINERVA-Australis.**

**Key words:** instrumentation: spectrographs – instrumentation: photometers – techniques: photometric – techniques: radial velocities – techniques: spectroscopic – planets and satellites: detection – (stars:) planetary systems

**Online material:** color figures

## 1. Introduction

There has long been interest in the discovery of planets around other stars. Early attempts to find such worlds, however, got off to a slow and rocky start with several exoplanetary detection claims being either later retracted, or never confirmed, such as the proposed planets orbiting 70 Ophiuchi (Jacob 1855), Barnard’s Star, (van de Kamp 1963; Gatewood 1995), and the pulsar PSR B1829-10 (Bailes et al. 1991; Lyne & Bailes 1992)). It took until the announcement of the first confirmed exoplanet orbiting a Sun-like star in 1995 (51 Pegasi b; Mayor & Queloz 1995) to truly kick off the “Exoplanet Era.”

In the years immediately following that discovery, the number of confirmed exoplanets grew slowly. As we have become ever more adept at finding new planets, however, the number known has grown exponentially, especially over the last decade. This is due, in large part, to the extremely successful *Kepler* mission launched by NASA in 2009 (Koch et al. 2010) to search for planets via their transits. The spacecraft’s four year primary mission, together with its more recent K2 program extension (Howell et al. 2014), confirmed the existence of over 2500 planets,<sup>27</sup> including many that resemble nothing found in the solar system.

This incredible diversity includes the so-called “hot Jupiters” and “hot Neptunes” (e.g., Mayor & Queloz 1995; Charbonneau et al. 2000; Gillon et al. 2007; Bakos et al. 2010; Bayliss et al. 2013), planets moving on extremely eccentric orbits (e.g., Jones et al. 2006; Wittenmyer et al. 2017), planets with densities greater than iron and even osmium (e.g., Deleuil et al. 2008; Dumusque et al. 2014; Johns et al. 2018), or comparable to styrofoam (e.g., Faedi et al. 2011; Welsh et al. 2015; Pepper et al. 2017). Perhaps most surprisingly, *Kepler* revealed that planets between the size of Earth and Neptune (“super-Earths” or “mini-Neptunes”) are incredibly common, despite the fact that no analog exists in the solar system (e.g., Charbonneau et al. 2009; Barragán et al. 2018).

The primary goals of *Kepler* were to perform a detailed exoplanet census and to measure the frequency distribution function for planets around other stars. This was accomplished by continually monitoring  $\sim 150,000$  stars in the northern constellation of Cygnus for transits (Koch et al. 2010) for a period in excess of four years. Chief among *Kepler*’s results is the revelation that planets are ubiquitous, and that the majority of stars host small planets, with mini-Neptunes and super-Earths being the most common of those found on orbits of  $\leq 200$  days (Fressin et al. 2013). *Kepler* also revealed that Earth-sized planets ( $0.5 \leq R_p \leq 1.4 R_\oplus$ ) are particularly common around cool stars ( $T_{\text{eff}} \leq 4000$  K), with an occurrence rate of just over 50% (Dressing & Charbonneau 2013). Indeed, based on *Kepler* data, Dressing & Charbonneau estimated the

occurrence rate of Earth-size planets in the habitable zone as  $0.15^{+0.13}_{-0.06}$  planets per cool star. This suggests that the nearest transiting Earth-size planet in the habitable zone could be located within 21 pc of Earth.

Despite the stunning success of the *Kepler* mission, little is known about the compositions, masses, and densities of the majority of the *Kepler* planets. The reason for this is that the majority of the planet-hosting stars identified by *Kepler* are either too faint for further follow-up investigations using existing facilities, or would require an inordinate investment of time on large telescopes. Because of the significant resources that are required to convert the large number of *Kepler* candidates into confirmed planets and measure their masses, only about 50% of *Kepler*’s candidate planets have been confirmed, and of these, only  $\sim 10\%$  have mass measurements.<sup>28</sup>

On 2018 April 18, NASA launched its next-generation exoplanet finder, the *Transiting Exoplanet Survey Satellite* (*TESS*; Ricker et al. 2015). Unlike *Kepler*, which observed a single small region on the sky, *TESS* expands the search for planets to nearly the entire sky. *TESS* consists of four wide-angle cameras that each have a field of view of  $24^\circ \times 24^\circ$ , yielding a total field of view for *TESS* of  $96^\circ \times 24^\circ$ . The spacecraft is oriented such that one of the cameras is centered on one of the ecliptic poles while the others are pointed progressively closer to the ecliptic. *TESS* will monitor each  $24^\circ$  wide strip on the celestial sphere for a period of 27 days before moving on to an adjacent strip of the sky. As such, the majority of stars will be observed for 27 days, while those closer to the ecliptic poles will be observed for longer. As a result of this strategy, stars within  $\sim 12^\circ$  of the ecliptic poles will be observed for a year. *TESS* will observe the southern ecliptic hemisphere in its first year of operation before moving on to the northern ecliptic hemisphere in the second year of its mission.

Throughout the course of its initial two-year mission, *TESS* will survey approximately 200,000 of the brightest stars in the sky with a cadence of two minutes. Planets discovered around these bright stars will be suitable for ground-based follow-up observations to both confirm their existence and facilitate their characterization (e.g., Huang et al. 2018; Gandolfi et al. 2018). Data will also be returned on an additional 20 million stars from “full-frame images”, taken with a cadence of 30 minutes. As a result, there will be no shortage of planet candidates coming from *TESS* that will need follow-up observations. Additionally, stars observed by *TESS* will be, on average, a hundred times brighter than those observed by *Kepler*, and it is expected that *TESS* will deliver a yield of thousands of new planets orbiting bright stars.

With the expected flood of planet candidates being found by *TESS* to be orbiting bright stars, dedicated facilities are urgently

<sup>27</sup> See <https://exoplanetarchive.ipac.caltech.edu/> for the latest tally.

<sup>28</sup> Determined using the NASA Exoplanet Archive (<https://exoplanetarchive.ipac.caltech.edu/>). There are 2347 confirmed *Kepler* planets and 244 of them have mass measurements listed in the table.

needed to confirm the candidates and characterize them. The radial velocity technique is the primary method to deliver the critical planetary parameters, such as mass and orbital eccentricity, that are required to properly characterize the planetary system. Most of the existing facilities capable of carrying out the required high-precision radial velocity measurements, however, are subject to intense competition and scheduling constraints (particularly on shared large telescopes). Traditionally, radial velocity programs are allocated blocks of time (a couple of weeks to a month) on large telescopes during bright nights (though some such as the Hobby-Eberly Telescope and WIYN are working to facilitate queue and cadence observations).

With the expected large number of planet candidates to be delivered by *TESS*, the most exciting of which will be low-mass planets with orbital periods exceeding one month (in particular those planets orbiting within the habitable zone around M-dwarf stars), this strategy simply will not work. This is the primary cause of the significant bottlenecks experienced during the follow-up work carried out on *Kepler* candidates (Fleming et al. 2015).

Similarly with *TESS*, we will be in a situation where we have too many planets, and too few telescopes to confirm them.

To address this bottleneck issue with *TESS* follow-up, we are commissioning the MINERVA-Australis facility at the University of Southern Queensland's Mount Kent Observatory (MKO). MINERVA-Australis builds on the template and groundwork of a similar facility in the Northern Hemisphere called MINERVA (MINiature Radial Velocity Array) located at Mt. Hopkins in the Arizona desert (Swift et al. 2015). Whereas the primary goal of the northern MINERVA observatory is to search for small-mass planets orbiting nearby bright stars through high-cadence radial velocity observations, MINERVA-Australis will be primarily focused on supporting the follow-up work of NASA's *TESS* mission.

The MINERVA-Australis collaboration consists of the University of Southern Queensland as the primary investigator along with the University of Texas at Austin, Massachusetts Institute of Technology, University of California at Riverside, University of Louisville, George Mason University, the University of New South Wales, University of Florida, and Nanjing University as co-investigators and major funding partners in this project. It is also a participating member of the *TESS* Follow-up Observing Program (TFOP<sup>29</sup>) Working Group (WG). The primary goal of TFOP WG is to coordinate the follow-up observations of *TESS* planet candidates to measure masses for 50 transiting planets smaller than four Earth radii. Additionally, TFOP WG is fostering communication and coordination within its network of participants and community at large to optimize the follow-up work of *TESS* planet candidates and minimize wasteful duplication of observations and analysis. MINERVA-Australis is primarily involved in two of the TFOP Sub Groups (SGs), SG2 for reconnaissance spectroscopy and SG4 for precision radial velocity work.

Secondary science objectives for the MINERVA-Australis project include the measurement of the spin-orbit alignment of planetary systems through radial velocity and Doppler tomography observations of the Rossiter-McLaughlin effect (Rossiter 1924; McLaughlin 1924; Queloz et al. 2000; Johnson et al. 2014; Addison et al. 2018). Spin-orbit alignments can provide key insights into the formation and migration histories of exoplanets (e.g., see, Lin et al. 1996; Bodenheimer et al. 2000; Ford & Rasio 2008; Naoz et al. 2011; Wu & Lithwick 2011), in particular hot (Crida & Batygin 2014; Winn & Fabrycky 2015) and warm Jupiters (Dong et al. 2014), and compact transiting multi-planet systems (Albrecht et al. 2013; Wang et al. 2018a). Additionally, Doppler tomography observations can aid in the confirmation of transiting planet candidates orbiting rapidly rotating stars that are not amenable to precise radial velocity observations (Johnson et al. 2014). Another science goal is to carry out long-term radial velocity monitoring of planetary systems found by *TESS*. Such observations could reveal the existence of nontransiting, long-period planets that can provide constraints on the migration history of the inner transiting planet(s) (e.g., Otor et al. 2016; Christiansen et al. 2017; Almenara et al. 2018).

While spectroscopy and radial velocity observations are the primary focus of MINERVA-Australis, high-precision and high-cadence photometry is also an important component of this project.

Fluctuations observed in the out-of-transit photometry of a star can be used to disentangle the radial velocity variations that are produced by stellar activity, such as from starspots and from the suppression of convective blueshift occurring in active regions on the stellar surface, from planetary signals (Boisse et al. 2011). This is particularly the case when photometry and radial velocity data are obtained simultaneously (Haywood et al. 2014), as can be done with MINERVA-Australis. Such data will provide a better understanding of the effects of stellar activity on radial velocity observations, enabling the detection of sub-Neptune mass planets and more accurate determinations of their masses.

Simultaneous photometry is also useful when carrying out Rossiter-McLaughlin effect observations. These observations are typically carried out several hundred orbital periods after the last published transit in the literature and the ephemerides have usually become out of date. Simultaneous photometry can be used to lock down the transit ingress, mid, and egress times needed for properly analyzing Rossiter-McLaughlin data. Additionally, stellar activity can deform the Rossiter-McLaughlin signal, which can cause significant variations in the measured spin-orbit angle (up to  $\sim 42^\circ$ ) from transit to transit (Oshagh et al. 2018). Simultaneous photometry can provide information about the properties of the active regions on a stellar surface that will allow for better modeling of the Rossiter-McLaughlin signal (Oshagh et al. 2018).

While it is expected the majority of transiting planets detected by *TESS* will come from the pre-selected bright stars with a two minute cadence, undoubtedly some transit detections will come from the full-frame images that are taken at a 30 minute cadence.

<sup>29</sup> <https://tess.mit.edu/followup/>

**Figure 1.** Google Maps image of the Mount Kent Observatory showing the location of the MINERVA-Australis telescopes and building. (A color version of this figure is available in the online journal.)

These planets will require follow-up transit photometry to help improve the transit parameters such as the orbital period. MINERVA-Australis will be utilized for this task as such planet candidates are found. We will also be using photometry to search for transit timing variations through photometric transit observations that could reveal the presence of additional planets (Malavolta et al. 2017; Saad-Olivera et al. 2017) as well as transit observations to keep the transit ephemerides up-to-date for *TESS* planets.

Other ancillary science goals include observations of predicted solar system occultation events. Such observations have yielded improved information on the size, shape, and albedo of small solar system objects (Sicardy et al. 2011a, 2011b; Ortiz et al. 2012) as well as led to the discovery of ring systems around some of these minor bodies (Braga-Ribas et al. 2014; Ortiz et al. 2017). We are also planning on continuing the radial velocity follow-up of targets that were originally observed as part of the Anglo-Austrian Planet Search program (AAPS; e.g., Tinney et al. 2011; Wittenmyer et al. 2014) with the aim of extending the radial velocity data-set baseline to enable the detection of longer orbital period ( $\geq 5$  yr) planets. By continuing the AAPS legacy survey, our goal is to expand the population of known Jupiter or Saturn analogs and determine the degree to which the solar system is unusual or unique.

We have organised the paper as follows: Section 2 provides an overview of the MKO and the reasons for selecting the site for MINERVA-Australis. Section 3 describes the MINERVA-

Australis facilities and hardware, including the telescopes and enclosures, spectrograph, camera, and control building. In Section 4, we present the first science results from follow-up photometric transit observations of four transiting planets, including WASP-2b, WASP-44b, WASP-45b, and HD 189733b. In Section 5 we summarize the MINERVA-Australis facility, goals, and future work.

## 2. Mount Kent Observatory

The MINERVA-Australis facility is being commissioned at the MKO, located in the Darling Downs in Queensland, Australia, approximately 25 km south-southwest of Toowoomba and 120 km west-southwest of Brisbane. It is situated at an altitude of  $\sim 680$  m and a latitude and longitude of  $27^{\circ}47'53''$  S and  $151^{\circ}51'20''$  E. The site already houses three telescopes of the Shared Skies project, operated jointly between the University of Louisville, KY, and the University of Southern Queensland: the 0.1 m aperture wide field OMara robotic telescope, used for education, and two PlaneWave Instrument telescopes (a CDK20 and a CDK700; CDK: corrected Dall-Kirkham) used for KELT<sup>30</sup> and *TESS* precision exoplanet transit photometry follow-up. Figure 1 shows a Google Maps image of the MINERVA-Australis telescope sites, building location, and other facilities on the MKO.

<sup>30</sup> The Kilodegree Extremely Little Telescope survey (e.g., Pepper et al. 2007, 2012; Soutter et al. 2016).

The Mount Kent site was selected based on good weather conditions with an average of  $\sim 296$  clear/mostly clear nights per year, reasonably good seeing conditions (estimated to be around  $1.6''$  from seeing measurements reported by the facilities at the site), and existing facilities and support. The weather data have been obtained from the Bureau of Meteorology website<sup>31</sup> using the Oakey Aero weather station (a nearby weather station with 35 years of historic climate data) located about 44 km from Mount Kent. Conditions at the Oakey weather station should serve as a good proxy for the conditions observed at Mount Kent and give a good estimate of the number of usable nights. Therefore, we anticipate  $\sim 296$ <sup>32</sup> nights per year with observable weather conditions with at least an average of 6.7 usable hours and a median seeing of  $1.6''$ .

### 3. Facilities

In this section, we give details of the MINERVA-Australis hardware, highlight the ways in which our new facility differs from the northern MINERVA facility (Swift et al. 2015), and discuss the reasoning behind those choices.

#### 3.1. Telescopes and Enclosures

MINERVA-Australis will comprise up to six independently operated 0.7 m PlaneWave CDK-700 altitude/azimuth mounted telescopes<sup>33</sup> (see Figure 2), arranged in a semi-circle, all feeding light to a single Kiwispec<sup>34</sup> high-resolution spectrograph (Barnes et al. 2012). In contrast, northern MINERVA comprises four 0.7 m PlaneWave CDK-700 telescopes (equivalent to a single 1.4 m diameter aperture versus a single 1.7 m aperture for MINERVA-Australis). The additional two telescopes in the MINERVA-Australis array provide us with  $1.5\times$  the collecting area and  $\sim 1.2\times$  increase in signal-to-noise ratio over northern MINERVA. The PlaneWave CDK-700 telescope has a compact design that is 2.4 m tall when pointed at zenith and a radius of maximum extent of 1.5 m. The telescopes use a CDK optical setup to remove off-axis coma, astigmatism, and field curvature. Over a three minute interval, the telescopes have a pointing accuracy of  $10''$  rms, pointing precision of  $2''$ , and a tracking accuracy of  $1''$ . The telescopes are controlled through a PlaneWave interface (PWI). They also have a very fast slew rate of  $15^\circ$  per second, enabling the telescopes to slew between any two points on the sky within 10 seconds. For a complete discussion of the PlaneWave CDK-700 telescopes hardware and specifications, we refer the reader to the northern MINERVA facility publication (Swift et al. 2015). Here we provide a summary of the important aspects of the telescopes and list the specifications in Table 1.

<sup>31</sup> <http://www.bom.gov.au/>

<sup>32</sup> This time excludes additional factors like unusually high humidity, dust storms, and maintenance.

<sup>33</sup> <http://planewave.com/products-page/cdk700>, three installed as of 2019 February.

<sup>34</sup> <https://www.kiwistaroptics.com/>

Each of the PlaneWave CDK-700 telescopes is housed in its own AstroHaven Enterprises 12.5 ft (3.81 m) diameter dome<sup>35</sup>, as shown in Figure 3. The dome is designed for remote and robotic operations from anywhere in the world. It can fully open, giving full access to the sky, and can achieve thermal equilibrium very rapidly, reducing the effects of “dome seeing.” The dome can also open rapidly, in approximately 20 s, with each hemisphere opening independently. In contrast, the northern MINERVA uses an “Aqawan” enclosure that was developed by Las Cumbres Observatory engineer Annie Kirby. A rectangular Aqawan can house two PlaneWave CDK-700 telescopes whereas each AstroHaven dome for MINERVA-Australis houses one Planewave telescope that can be independently operated.

The AstroHaven domes are powered by 240 V/15 A three-phase power which is converted to 24V DC within its control panel and the telescopes by a 240 V/10 A power supply. This is then connected to an internal uninterruptible power supply (UPS) and stand-by generator, ensuring the dome can close if the site loses power and we can cease observing until power is restored. Communication to the domes are established by a TCP/IP interface and are controlled through ASCII string commands. We are currently in the process of implementing an automated dome closure protocol in case communication is lost to the domes and telescopes for remote observing carried out in the future.

A web camera is situated inside each of the domes to provide a live video feed to the user. A weather station is located approximately 10 m to the north of the MINERVA-Australis building which provides real-time temperature, humidity, wind speed, and wind direction measurements. In addition, it has a rain sensor that will alert the user to rain and send a signal to control to close up the dome.

#### 3.2. Spectrograph

All of the telescopes in the MINERVA-Australis array simultaneously feed a single Kiwispec R4-100 high-resolution spectrograph (Barnes et al. 2012) via fiber optic cables. The specifications for the spectrograph are provided in Table 2. The spectrograph is bench-mounted and housed in an insulated, environmentally controlled enclosure. Kiwispec uses an R4 echelle for the primary dispersion while a volume-phase holographic (VPH) grism is used for the cross-dispersion. The fibers are aligned in the cross-dispersion direction of the spectrometer, and form seven individual echelle traces that are imaged on a  $2k \times 2k$  detector. The detector has a wavelength coverage from 500 to 630 nm over from 26 echelle orders with a resolution of  $R \approx 80,000$ .

We currently use  $50 \mu\text{m}$  circular fiber cables with a  $70 \mu\text{m}$  cladding diameter that are butt-coupled to  $50 \mu\text{m}$  circular fibers

Characteristics	
Spectral resolution	80,000
Wavelength range	500 nm–630 nm
Echelle orders	26
Detector size	2k $\times$ 2k
Cross-disperser	Anamorphic VPH grisms
Beam diameter	100 mm (at echelle grating), 33mm (at cross-disperser)
Main fibers	8 $\times$ 50 $\mu$ m circular fibers (six science and two calibration)
Average sampling	3.5 pixel per FWHM
Calibration	Simultaneous ThAr lamp
Environment for main optics	Vacuum operation, 1 mK temperature stability
Environment for camera optics	Pressure sealed operation, 20 mK temperature stability
Long-term instrument stability	Goal of 1 m s <sup>-1</sup>

and a numerical aperture of 0.22 to feed scrambled light to the spectrograph. The five science fibers are bracketed by two additional calibration fibers that provide a simultaneous and stable thorium–argon wavelength calibration source. Octagonal fibers will replace the circular fibers in the final configuration of the instrument by mid-2019. Northern MINERVA in contrast uses octagonal fibers and has four science fibers for the four telescopes in the array. It also use an iodine absorption cell placed in the light path instead of a thorium–argon lamp for wavelength calibration source. While the Minerva design was optimized for iodine work, we currently use thorium–argon, as

Pixel well depth...	150,000 $e^-$
Operating temperature	−100 °C
Dark current ( $e^- \text{ pixel}^{-1} \text{ s}^{-1}$ )	0.0003
Pixel readout rates	5.0, 3.0, 1.0, and 0.05 MHz
Read noise ( $e^-$ )	
0.05 MHz	8.7
1 MHz	22.2
3 MHz	40.2
5 MHz	70.3
Wavelength regions (QE ≥ 50%)	350–975 nm
Peak quantum efficiency	750 nm

it provides a good wavelength reference required for precision radial velocity work ( $<1 \text{ m s}^{-1}$ ; Mayor et al. 2003). Additional reasons for choosing thorium-argon over iodine cell include better throughput of the system and no contamination of the spectra from iodine absorption lines. More details on the commissioning and performance of the MINERVA-Australis Kiwispec spectrograph will be presented in a follow-up paper.

### 3.3. Photometric Camera

The MINERVA-Australis telescopes can each be equipped with an Andor iKon-L 936 camera,<sup>36</sup> the specifications are provided in Table 3. Switching between our standard spectroscopic mode to the photometric observing mode is done through a simple flipping of the telescope’s M3 mirror in the PWI software interface to direct stellar light to the imaging camera instead of the fiber that feeds the KiwiSpec spectrograph.

As of 2018 September, one photometric camera is present on Telescope 1. Further cameras will be acquired subject to funding. The camera consists of  $2048 \times 2048$  square  $13.5 \mu\text{m}$  pixels that provides an on-sky field of view of 20.9', contain a deep depletion sensor with fringe suppression (BEX2-DD), and have an extended range dual Anti-Reflection (AR) coating. The deep depletion sensor enables the camera to be sensitive to light from the near-ultraviolet to the near-infrared ( $1 \mu\text{m}$ ) for precision photometry. The cameras are also equipped with a five-stage thermo-electric cooling system that allows the sensor to be cooled down to  $-100^\circ\text{C}$ , keeping dark current to a minimum, without having to use liquid nitrogen.

Each telescope uses an CenterLine Color 10 Position Color Filter Wheel (FLI CL1–10 CFW) filter wheel, with second-generation Sloan  $g'2$ ,  $r'2$ ,  $i'2$ ,  $z'2$  filters, and a narrow-band  $\text{H}\alpha$

filter planned for a later date. We chose these standard sets of filters to provide us with flexibility for our transit observations while observing in variable conditions and for our other auxiliary programs.

The Sloan  $r'$  filter is used for most transit photometric observations. For the transit observations of WASP-2b, WASP-44b, and WASP-45b, we used the  $r'$  filter. This filter provides good throughput while minimizing atmospheric extinction effects. We used the  $z'$  band filter for observing the transit of HD 189733b since the star is quite bright ( $V = 7.6$ ) and the quantum efficiency of our camera is a factor of 2 below peak. The  $z'$  filter is suitable for observing bright targets without reaching the non-linearity point or pixel saturation level for the detector at reasonable exposure lengths.

To obtain high-precision photometry at high cadence with reasonably short readout times, our observations are carried out using the 1.0 MHz pixel readout mode. The total readout time for the detector in this mode is  $\sim 4 \text{ s}$  with a readout noise of  $22.2 e^-$ .

### 3.4. Control Building

While MINERVA-Australis is primarily designed for automated observing, it can be controlled both on site and remotely. The \$2 million control facility features a purpose-built class 100,000 clean room that houses the spectrograph, with the critical components inside a vacuum chamber and thermally stabilized to  $\pm 0.01 \text{ K}$ . Additionally, it contains an UPS room where power for the entire MINERVA-Australis facility is routed through for an uninterruptible power supply and a control room that houses the computers and network equipment.

## 4. First Science Results with MINERVA-Australis

While the primary focus of MINERVA-Australis will be the radial velocity follow-up of transiting planet candidates found by *TESS*, five secondary photometric science goals include: photometric follow-up of *TESS* and other transit survey planets to ensure that the ephemerides are up-to-date and accurate for future follow-up observations (e.g., Hoyer et al. 2016; Wang et al. 2018b), ruling out potential false positives from nearby eclipsing binaries (Collins et al. 2018; Ziegler et al. 2018), searching for transit timing variations (Malavolta et al. 2017; Saad-Olivera et al. 2017) and longer-period planets (e.g., Otor et al. 2016; Almenara et al. 2018) and follow-up of planets found by radial velocity observations from the AAPS (e.g., Tinney et al. 2011; Wittenmyer et al. 2014). In addition, target-of-opportunity observations of high-priority solar system occultation events (e.g., Sicardy et al. 2011a; Ortiz et al. 2012, 2017) are also planned using a very high-cadence camera that will be installed at a future date. With this in mind, we conducted high-precision photometry observations of four known transiting exoplanets as part of the commissioning operations and to benchmark our photometric precision.

#### 4.1. High-precision Photometry

We carried out high-precision photometry for four known transiting planets exoplanets, WASP-2b, WASP-44b, WASP-45b, and HD 189733b using the first telescope that was installed at the MINERVA-Australis site. Photometry was obtained using the Andor iKON-L camera and the Sloan  $r'$  (WASP-2b, WASP-44b, and WASP-45b) and  $z'$  (HD 189733b) filters as discussed in Section 3.3. Maxim DL<sup>37</sup> was used to control the camera while the telescope was controlled through the PWI interface. No active guiding was used during the four transit observations. Active guiding is a feature that will be implemented soon and used for future transit photometry observations.

A series of calibration frames were obtained for each of the transit observations and standard photometric reduction procedures were followed to produce our calibrated science images. We then extracted photometry from our science images using the multi-aperture mode of AstroImageJ (Collins & Kielkopf 2013; Collins et al. 2017), which uses simple differential aperture photometry and sky-background subtraction. We then re-centered the apertures on individual stellar centroids in each image using the center-of-light method (Howell 2006). Details on the aperture size and the comparison stars used to produce the photometry are described in the respective subsections. The choice of comparison stars for each transit observation was based on their counts, trends, and the amount of available stars in the image. The AstroImageJ differential photometry processor

automatically removes any comparison star trends by comparing the flux in its aperture to the sum of the flux in all other comparison star apertures (Collins et al. 2017).

All fits were performed with EXOFASTv2 (Eastman et al. 2013, Eastman 2017, Eastman et al. 2019), which uses a differential evolution Markov chain Monte Carlo to model the stellar system by simultaneously fitting our MINERVA transit, detrending with airmass; the discovery radial velocities from HIRES (HD189733), SOPHIE (WASP-2), and CORALIE (WASP-44 and WASP-45); the spectral energy distribution (SED) using catalog photometry from Tycho (Høg et al. 2000), 2MASS (Cutri et al. 2003), WISE (Cutri et al. 2013), and Gaia (Gaia Collaboration et al. 2018); and the MIST stellar evolutionary models (Dotter 2016; Choi et al. 2016). For each fit, we used Gaussian priors on  $T_{\text{eff}}$  and [Fe/H] from the the high resolution spectroscopy in their respective discovery papers, as well as Gaussian priors on the parallax from Gaia DR2, adding  $82 \mu$  as to correct for the systematic offset found by Stassun & Torres (2018) and adding the  $33 \mu$  as uncertainty in their offset in quadrature to the Gaia-reported uncertainty. We applied an upper limit on the V-band extinction from the Schlafly & Finkbeiner (2011) dust maps at the location of each target.

The priors and broadband magnitudes we used for each system are summarized in Table 4, and the results for each system are summarized in Table 5. In nearly all cases (unless otherwise noted), our results are consistent with the literature values, and in some cases our uncertainties are smaller, owing primarily to the Gaia constraint on the stellar parameters, but also to the longer baseline between the RVs and our transits.

#### 4.2. Transit Observation of WASP-2b

We observed the transit of WASP-2b (Collier Cameron et al. 2007), starting photometric observations on the evening of 2018 August 8 at approximately 10:30 UT, and continuing observing until 13:15 UT, obtaining 304 science frames with a cadence of 35 s. WASP-2 is a moderately faint ( $V = 11.98$ ) K1V spectral type star hosting a hot Jupiter with an orbital period of  $P = 2.15$  days (Collier Cameron et al. 2007). The sky was photometric with clear conditions during the transit observations and seeing of  $3.5''$ .

From our calibrated science frames, we extracted differential photometry using the AstroImageJ reduction pipeline by first selecting an aperture of 15 pixels ( $9.15''$ ) and a sky annulus with an inner radius of 30 pixels and an outer radius of 40 pixels around four stars, including WASP-2b.

Once we extracted the photometry, we fit the data using EXOFASTv2 to produce the final light curve of WASP-2b. Figure 4 shows the raw light curve, the best-fit transit model with the de-trended light curve, and the residuals from the fit. The rms scatter of the residuals from the fit to our light curve is 0.95 mmag or 950 parts per million (ppm).

Our results for WASP-2b are in general agreement with those of Collier Cameron et al. (2007). The mid-transit time we measured ( $T_C = 2458339.00236^{+0.00042}_{-0.00051}$ ) is  $-0.00876$  days 12.6 min earlier than the predicted time of  $T_C = 2458339.01112 \pm 0.0092$ . This is in agreement with the Collier Cameron et al. (2007) predicted

**Figure 4.** Transit light curve data for WASP-2b; the top light curve is normalized but not de-trended and the bottom one is normalized and de-trended with a best-fit model overplotted. The bottom panel shows the residuals to the best-fit model.  $T_C$  is the mid-transit time.

(A color version of this figure is available in the online journal.)

**Figure 5.** Same as Figure 4, but for the light curve of WASP-44b.  
(A color version of this figure is available in the online journal.)

mid-transit time when the accumulated uncertainty from 2020 orbital cycles since the last published ephemeris has been taken into account. Our measurement updates the published ephemeris, and extends the time baseline of WASP-2b transit photometry to approximately 12 years.

The orbital period we measured is  $P = 2.152160^{+0.000025}_{-0.000020}$  days, which does not agree to within  $3\sigma$  of the published period of  $P = 2.152226 \pm 0.000004$  days (difference of 0.000066 days or  $\sim 3.3\sigma$ ). The source of this discrepancy is not clear and Turner et al. (2017) found no evidence for transit timing variations. The results for our other parameters are in agreement with those of Collier Cameron et al. (2007).

#### 4.3. Transit Observation of WASP-44b

Transit observations of WASP-44b were started on the night of 2018 August 7 at approximately 12:35 UT, nearly an hour before transit ingress. We continued to observe WASP-44b for about an hour after egress, observing until 16:10 UT, collecting 62 science frames with a cadence of 205 s. WASP-44b is a relatively faint ( $V = 12.9$ ) G8V spectral type star that hosts a hot Jupiter with an orbital period of  $P = 2.42$  days (Anderson et al. 2012). Our observations were done under clear skies and seeing of  $4.1''$ .

Photometry was extracted using the *AstroImageJ* reduction pipeline following the same procedure as detailed for WASP-2b and using the same size aperture and sky annulus around our target and comparison stars. We then fit the data using EXOFASTv2 to produce the final light curve of WASP-44b (Figure 5). The rms scatter of the residuals from the fit to our light curve is 1.18 mmag (1180 ppm). The best-fit transit model with the de-trended light curve and the residuals from the fit are shown in Figure 5. Table 5 lists the resulting median parameter values and  $1\sigma$  uncertainties.

**Figure 6.** Same as Figure 4, but for the light curve of WASP-45b.  
(A color version of this figure is available in the online journal.)

Overall our results for WASP-44b are in good agreement with those of Anderson et al. (2012) to within  $1\sigma$ . The mid-transit time we measured ( $T_C = 2458338.10197 \pm 0.00036$ ) is 0.0089 days or 12.8 min later than the predicted time of  $T_C = 2458338.09307 \pm 0.01040$ , but is in agreement with Anderson et al. (2012) when the accumulated uncertainties from 1198 orbital cycles since the last ephemeris have been taken into account for the mid-transit time uncertainty. Thus our measurements do agree with the predicted time and suggest that there is no significant deviation in the transit time. We have now provided an update to the published ephemeris that extends the time baseline of WASP-44b transit photometry to approximately eight years.

#### 4.4. Transit Observation of WASP-45b

On the night of 2018 August 8, we observed another transiting planet, WASP-45b, after observations of WASP-2b had finished. For this transit, observing commenced at 13:55 UT (just over an hour before ingress) and continued until 17:20 UT (around two hours after egress). In total we obtained 219 science frames with a cadence of 55 s. WASP-45 is a moderately faint ( $V = 12.0$ ) K2V spectral type star hosting a hot Jupiter with an orbital period of  $P = 3.13$  days (Anderson et al. 2012). WASP-45b was observed under similarly clear skies; however, the seeing was worse ( $6.1''$ ).

We followed the same overall procedure for extracting photometry as described in Section 4.1. In total nine comparison stars were used for deriving the photometry. The raw light curve along with the best-fit model with the de-trended light curve and the residuals from the fit are shown in Figure 6. The rms scatter from our best-fit light curve model is 1.2 mmag (1200 ppm).

**Figure 7.** Same as Figure 4, but for the light curve of HD 189733b. (A color version of this figure is available in the online journal.)

Our results for WASP-45b are generally in good agreement with those of Anderson et al. (2012). The mid-transit time we measured ( $T_C = 2458339.14264^{+0.00032}_{-0.00031}$ ) is  $-0.00982$  days ( $-14.1$  min) earlier than the predicted time of  $T_C = 2458339.15246 \pm 0.00058$  from Anderson et al. (2012) but is in agreement with their result when the uncertainty on the orbital period is taken into account after 927 orbital periods. Our transit observation now extends the published ephemeris to a time baseline of approximately eight years.

There are 1 to  $1.5\sigma$  discrepancies seen in  $T_{14}$ ,  $i$ ,  $R_*$ , and  $R_p$ . The origin of this discrepancy is not understood but could potentially be from stellar activity as Anderson et al. (2012) reported WASP-45 to be chromospherically active.

#### 4.5. Transit Observation of HD 189733b

We observed the transit of HD 189733b on the night of UT 2018 August 4 with photometric observations starting at approximately 10:00UT (about one hour before ingress). We continued observing the target until approximately 30 minutes after egress (13:15UT), obtaining 517 observations with a cadence of  $\sim 7$  s. HD 189733 is a very bright ( $V = 7.6$ ) K2 spectral-type star hosting a hot Jupiter with an orbital period of  $P = 2.22$  (Bouchy et al. 2005). The observations were conducted under clear skies and seeing of  $2.6''$ .

Following the procedure described in Section 4.1, we extracted photometry using the AstroImageJ by first selecting an aperture of 20 pixels ( $12.3''$ ) and a sky annulus with an inner radius of 35 pixels and an outer radius of 45 pixels around 14 stars, including HD 189733. The raw and de-trended light curve with the best-fit model along with the residuals from the fit are shown in Figure 7.

The rms scatter of the residuals from the fit to our light curve is 5.2 mmag (5200 ppm).

Our results for HD 189733b are in good agreement with those of Bouchy et al. (2005), Bakos et al. (2006), Southworth (2010), and Baluev et al. (2015). The mid-transit time we measured ( $T_C = 2458334.99057^{+0.00071}_{-0.00073}$ ) is  $-0.0024$  days ( $-3.5$  min) earlier than the predicted time of  $T_C = 2458334.9930000 \pm 0.0000088$  from Baluev et al. (2015) but is in agreement with their result when the uncertainty on the orbital period is taken into account after 1974 orbital periods. HD 189733b now has an ephemeris baseline of approximately 13 years.

## 5. Conclusions and Future Work

We have built a dedicated observatory for high-precision photometric and spectroscopic observations of exoplanetary systems, primarily in support of the NASA *TESS* mission. MINERVA-Australis is the only Southern Hemisphere facility with such capabilities that is fully dedicated to *TESS* follow-up.

In this work, we have presented initial photometric science demonstration results. Based on these results, we expect to contribute high-precision ( $\leq 1.0$  mmag) photometry for *TESS* targets brighter than  $V = 13$  with exposures of under five minutes. This is comparable to the MINERVA North photometric commissioning results (Swift et al. 2015) and to other ground-based follow-up programs such as HATSouth carried out on the Las Cumbres Observatory 1 m telescopes, the Danish 1.54 m telescope, the Chilean–Hungarian Automated 0.7 m Telescope, and Perth Exoplanet Survey 0.3 m Telescope which obtained photometric precision of 0.9–3.0 mmag for  $V \leq 13$  targets (see, e.g., Hartman et al. 2019). At the time of writing, the KiwiSpec spectrograph is being commissioned. In a forthcoming paper (D. J. Wright et al. in preparation), we will fully describe the acquisition and analysis of spectroscopic data at MINERVA-Australis, and we will present data demonstrating our radial velocity precision on standard stars and known exoplanets.

We are also in the process of enabling fully autonomous operations of the telescope array by customizing the existing automation software, MINERVA Robotic Software (Swift et al. 2015), developed for the MINERVA North array to suit our specific scientific goals and operational requirements.

In the future, we anticipate adding very high-cadence photometric capability, as each telescope can rapidly switch between photometric and spectroscopic modes via use of the two Nasmyth ports. With photometric cadence of up to 20 Hz, MINERVA-Australis will be able to capture occultation events of small solar system bodies (e.g., Braga-Ribas et al. 2014; Ortiz et al. 2015, 2017), allowing us to pursue time-critical target-of-opportunity research, in addition to pursuing our core goals in exoplanetary science.

This research was supported by the Australian Government through the Australian Research Council's Discovery Projects funding scheme (project DP180100972). MINERVA-Australis hardware is funded in part by the Australian government through the Australian Research Council, LIEF grants LE160100001. We acknowledge support from the Mount Cuba Astronomical Foundation. H.Z. is also grateful to the support from the Natural Science Foundation of China (NSFC grants 11673011, 11333002). P.P. acknowledges support from the the National Science Foundation (Astronomy and Astrophysics grant 1716202) and George Mason University start-up funds.

The MINERVA in the Northern hemisphere, which laid the groundwork for our installation, is made possible by generous contributions from its collaborating institutions and Mt. Cuba Astronomical Foundation, The David & Lucile Packard Foundation, National Aeronautics and Space Administration (EPSCOR grant NNX13AM97A), The Australian Research Council (LIEF grant LE140100050), and the National Science Foundation (grants 1516242 and 1608203). MINERVA hardware has been partially funded by the Australian Research Council's Linkage, Infrastructure, Equipment and Facilities funding scheme (project LE140100050). We are grateful to the Mt. Cuba Astronomical Foundation and the David and Lucile Packard Foundation for their generous funding of MINERVA hardware and personnel.
